## Acknowledgements

We are grateful to Lauren Clymer for patiently serving as the actor, and Katelyn Parisi, Gabrielle Pelle, Siobhan Treacy, and Bridget Whelan for their much appreciated help in collecting the data. Many thanks also to Cécile Schain, who provided dedicated technical assistance, as well as helpful comments on an earlier version of this manuscript.

## Abstract

Creating a mental image of one's own performance, observing someone else performing an action, and viewing a photograph of a completed action can all lead to the illusory recollection that one has performed this action. While there are fundamental differences in the nature of these three processes, they are aligned by the fact that they involve primarily or solely the visual modality. According to the source-monitoring framework, the corresponding visual memory traces can later be mistakenly attributed to self-performance. However, when people perform actions, they do not only engage vision, but also other modalities, such as auditory and tactile systems. The present study focused on the role of audition in the creation of false beliefs about performing an action and explored whether auditory cues alone—in the absence of any visual cues—can induce false beliefs and memories for actions. After performing a series of simple actions, participants either listened to the sound of someone performing various actions, watched someone perform the actions, or simultaneously both heard and saw someone perform them. Some of these actions had been performed earlier by the participants and others were new. A later source-memory test revealed that all three types of processing (hearing, seeing, or hearing plus seeing someone perform the actions) led to comparable increases in false claims of having performed actions oneself. The potential mechanisms underlying false action-memories from sound and vision are discussed.

## SOUND INFLATION

4

1  
2  
3 It is not unusual for people to mistakenly remember having done something—shut the  
4 window, put their keys in their bag—that they have not in fact done. People can be induced to  
5 falsely remember performing simple, everyday actions by imagining seeing themselves or by  
6 actually seeing someone else perform those actions (Goff & Roediger, 1998; Lindner,  
7 Echterhoff, Davidson, & Brand, 2010). Such work has not examined the impact of nonvisual  
8 processes, such as hearing the sounds of actions, on these false action-memories, however.  
9 The present study therefore explored whether sound alone in the absence of direct visual cues  
10 could trigger false action-memories and how false memories induced by sound compare to  
11 those induced by vision.  
12  
13  
14  
15  
16  
17  
18  
19  
20  
21  
22

23 In the typical paradigm to investigate false action-memories, participants perform  
24 various simple actions (e.g., *break the toothpick*; *roll the dice*) in Phase 1, and in Phase 2, they  
25 are presented with some of the actions they performed earlier (e.g., *break the toothpick*) and  
26 some new (non-performed) actions (e.g., *pour the water in the glass*). The kind of processing  
27 (e.g., imagination, observation) in this second phase has been varied between and within  
28 studies. Goff and Roediger (1998) showed that imagining performing simple actions in Phase  
29 2 inflated the number of false claims to have performed the actions oneself on a later, surprise  
30 source-memory test, the *imagination-inflation effect* (see also Garry, Manning, Loftus, &  
31 Sherman, 1996). Thus, people might falsely claim that they actually poured the water in the  
32 glass in Phase 1 when in fact they only imagined performing this action in Phase 2 (see also,  
33 e.g., Lampinen, Odegard, & Bullington, 2003; Thomas, Bulevich, & Loftus, 2003).  
34  
35  
36  
37  
38  
39  
40  
41  
42  
43  
44  
45  
46

47 Additional work has shown that watching other people perform actions via short  
48 video-clips in Phase 2 can have similar effects (Lindner et al., 2010; see also Nash, Wade, &  
49 Brewer, 2009). Thus watching someone else pour water in a glass can lead people to  
50 mistakenly claim that they themselves performed this action, dubbed the *observation-inflation*  
51 *effect* (see also Lindner, Schain, Kopietz, & Echterhoff, 2012; Schain, Lindner, Beck, &  
52 Echterhoff, 2012). Exposure to photographs of actions involving objects in their completed  
53

## SOUND INFLATION

5

1  
2  
3 states in Phase 2 (e.g., seeing a photo of an empty water bottle with a full glass of water  
4  
5 beside it) also induces false claims of having performed those actions, the *photo-inflation*  
6  
7 *effect* (Henkel, 2011). Taken together, imagining oneself, observing another person, as well as  
8  
9 looking at photos of completed actions all lead to false memories of having performed the  
10  
11 action.  
12

13  
14 Obviously, there are important differences between these three processes. For instance,  
15  
16 observing and watching are relatively passive, whereas imagining is more active; observation  
17  
18 inflation involves dynamic stimuli, whereas photo inflation involves static stimuli. However,  
19  
20 there is also one noticeable constant: Creating mental images, watching video-clips, and  
21  
22 viewing photos all involve the visual modality and result in visual memory traces, whether  
23  
24 they be self-generated or actually perceived. Indeed, it has been shown that memory  
25  
26 representations arising from imagination are often primarily visual in nature (e.g., Johnson,  
27  
28 Foley, Suengas, & Raye, 1988). In line with this assumption, Marsh, Pezdek, and Tam (2014)  
29  
30 recently showed that visual perspective during imagination alters imagination inflation.  
31  
32 Moreover, source memory for self- vs. other-performance decreased when visual similarity  
33  
34 between self- and other-performance increased (Hornstein & Mulligan, 2004). Therefore, a  
35  
36 better term to characterize these three inflation phenomena considering the basic feature they  
37  
38 have in common might be *visual(ization) inflation*.  
39  
40  
41  
42

43 This conceptualization of a visual(ization) inflation effect is further corroborated by  
44  
45 research highlighting the role of vision in perceptual illusions of agency and in memory  
46  
47 illusions. For instance, if a rubber arm is lying in front of a person while his or her own arm is  
48  
49 hidden, then viewing this arm being brushed (and simultaneously being brushed on the hidden  
50  
51 arm) evokes the illusion of feeling the touch of the brush that is applied to the rubber arm and  
52  
53 in addition generates an illusion of ownership of this arm (Botvinick & Cohen, 1998).  
54  
55 Moreover, showing people a doctored photo of a childhood event led many to believe that  
56  
57 they actually experienced the event (Wade, Garry, Read, & Lindsay, 2002), and showing  
58  
59  
60

1  
2  
3 people photographs of an unfamiliar scene increased beliefs that they had been to this location  
4  
5 (Brown & Marsh, 2008).  
6

7  
8 Taken together, the reported work suggests a critical role of visual cues in the creation  
9  
10 of false perceptions and memories of agency. At the same time, this research has largely  
11  
12 neglected the potential impact of other sensory cues, such as auditory ones. However, in one  
13  
14 study, participants viewed a video-clip of an artificial dummy head whose ear was caressed by  
15  
16 a brush (Kitagawa & Igarashi, 2005). The sound of that action was recorded by a microphone  
17  
18 in the ear of the dummy's head, and when it was played via headphones, people gave high  
19  
20 ratings when asked to agree to the item "I felt tickling on my own ear." Thus, confusions in  
21  
22 the perception of agency can arise on the basis of auditory cues alone. Accordingly, the  
23  
24 intriguing question that arises here is whether just listening to the sound of an action—without  
25  
26 seeing the action—can induce false memories of having performed the action oneself. Put  
27  
28 differently: Is there a *sound-inflation effect*?  
29  
30

31  
32 To address this, we had participants perform a series of actions and then either (a)  
33  
34 listen to the sound of someone performing actions, (b) watch someone performing actions, or  
35  
36 (c) both listen to the sound and watch someone performing actions. Two weeks later, they  
37  
38 had to remember which actions they actually performed.  
39

40  
41 According to the source-monitoring framework, people's judgments about the source  
42  
43 of a memory are influenced by its phenomenal features and how they compare to features  
44  
45 typical for memories derived from certain sources (Henkel & Carbuto, 2008; Johnson,  
46  
47 Hashtroudi, & Lindsay, 1993; Johnson & Raye, 1981). Research on false action-memories  
48  
49 has been in line with such an approach, emphasizing the role of sensory-perceptual cues in  
50  
51 creating this kind of memory illusion (e.g., Henkel, 2011; Lampinen et al., 2003; Thomas et  
52  
53 al., 2003). *Feature importation* gives rise to false beliefs and memories when features arising  
54  
55 from one experience (e.g., imagination or observation) are used when evaluating another  
56  
57  
58  
59  
60

1  
2  
3 experience (e.g., “Did I really do this?”) (Henkel & Franklin, 1998; Lampinen, Meier, Arnal,  
4  
5 & Leding, 2005; Lyle, Bloise, & Johnson, 2006).

6  
7 We propose that the inflation phenomena known to date specifically rely on a  
8  
9 misattribution of vivid visual memory-traces generated through imagination or observation to  
10  
11 self-performance. This approach can be easily applied to other sensory qualities: Just like  
12  
13 visual memory-traces, acoustical memory-traces from listening to another’s actions could be  
14  
15 misattributed to self-performance. Therefore, we expected to find a sound-inflation effect.

16  
17  
18 When one hears the sound of someone else performing an action, however, it not only  
19  
20 creates acoustical memory traces, but past work on cross-modal imagery suggests it might  
21  
22 also create visual memory traces (e.g., Spence & Deroy, 2013). That is, listening to the sound  
23  
24 of someone pouring water might lead one to visualize the action as well. We included a self-  
25  
26 report measure of concurrent imagery to investigate this possibility. Rather than potentially  
27  
28 bias participants to consciously consider concurrent mental imagery while hearing or seeing  
29  
30 the other person perform the actions, we had participants make a global assessment of  
31  
32 concurrent imagery after they completed the task.  
33  
34  
35

### 36 **Method**

#### 37 *Participants*

38  
39 Participants were 85 undergraduates from Fairfield University in CT (19 men, 66  
40  
41 women). Ages ranged from 18 to 23 years ( $M=19.21$ ,  $SD=1.07$ ). One participant failed to  
42  
43 return for the second session, and one was excluded because English was not the native  
44  
45 language, leaving a total of 83 subjects for analyses. This sample size allowed for a high  
46  
47 power ( $1-\beta \approx .95$ ) to detect an interaction of medium size ( $f = .25$ ) between our two independent  
48  
49 variables (for the within-subjects’ factor,  $r$  was set to .30).  
50  
51  
52

#### 53 *Design*

54  
55 The study used a 2 (encoding: performed, not performed) x 2 (exposure status in Phase  
56  
57 2: exposed, not exposed) x 3 (type of processing in Phase 2: heard only, watched only, heard  
58  
59  
60

## SOUND INFLATION

8

and watched) mixed-factorial design, with encoding and exposure status manipulated within-subjects, type of processing manipulated between-subjects, and proportion of false action-memories as the dependent variable.

*Materials and Procedure*

*Actions:* A total of 48 actions were generated: 32 critical actions with distinctive sounds (e.g., *sharpen the pencil, crack open the peanut*) and 16 filler actions. For a given subject, 16 of the critical actions were performed, and 16 were not performed (i.e., not presented) in Phase 1. Of the 16 actions of each type, 8 were again encountered in Phase 2, and 8 were not. A total of four sets were created to counterbalance these actions across conditions. For the 16 filler actions, 8 were performed in Phase 1, and 8 were not. Of the 8 actions of each type, 4 were presented again in Phase 2, and 4 were not. Filler actions were not counterbalanced, and therefore reported results only rely on the critical actions.

*Phase 1: Perform Actions:* Participants were tested individually at a table with 24 to-be-performed objects on it. They were told the study examined people's perceptions and thoughts about everyday actions. They were instructed that they would see an action statement for 5 seconds (e.g., *fold the paper bag*) and were to locate and place the object(s) in front of them and then perform the action once. After completing the action, the experimenter moved the objects back to their place on their table, and the next action statement appeared. The 16 critical and 8 filler actions were performed in random order.

*Phase 2: Exposure to Other's Actions:* Participants were told that the next task involved them making judgments about actions that someone else performed. Subjects were randomly assigned to one of three experimental conditions in which they either (a) only listened to the sound, (b) only watched, or (c) simultaneously both listened to and watched the person perform the actions. Their task was to count the number of times each action was performed.

## SOUND INFLATION

9

1  
2  
3 The color videos depicted a young woman in her early 20s wearing a black top at a  
4 table performing a series of actions with objects (see Figure 1). The shot was from a second-  
5 person perspective, as if she were sitting across the table from the participant, and it showed  
6 from her midsection to her neck, focusing on her torso, arms, and hands. The table held only  
7 the object(s) needed for a given trial.  
8  
9

10  
11  
12  
13  
14 Videos were either played with auditory input only, with visual input only, or with  
15 both auditory and visual input. Each trial started with the name of an action statement shown  
16 for 3 seconds (this was mainly to reduce ambiguity about what people would then hear in the  
17 listen-only condition). This was followed by presentation of the action being performed two to  
18 five times (depending on the length of the corresponding action) for a total of 10 seconds,  
19 followed by a prompt for participants to indicate the number of times the action was  
20 performed during the trial. During the course of Phase 2, each of the 16 critical (8 formerly  
21 performed, 8 non-performed) and 8 filler actions (4 formerly performed, 4 non-performed)  
22 appeared on four separate trials, making a total of 96 observed trials in Phase 2. All four trials  
23 containing 24 (16 critical plus 6 filler) actions were presented in a different randomized order  
24 with the restriction that the last video within one trial and the first video within the next were  
25 never identical.  
26  
27  
28  
29  
30  
31  
32  
33  
34  
35  
36  
37  
38  
39

40 After all trials, participants rated how difficult they found the counting task to be  
41 (1=*not at all difficult*; 7=*very difficult*), and indicated the percentage of trials on which they  
42 created mental images of what the actions looked like or sounded like while doing the  
43 counting task.  
44  
45  
46  
47  
48

49 *Phase 3: Memory Test:* Two weeks later, participants were given a surprise memory  
50 test on which they read various action statements and responded to the 48 events by noting  
51 either “yes, I performed the action” or “no, I did not perform the action.” Instructions  
52 emphasized that the task explicitly asked about the actions they themselves actually did with  
53 the objects on the table.  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 The memory test was comprised of all 48 actions in random order and hence consisted  
4 of 16 critical actions performed in Phase 1 (8 of which they had been exposed, and 8 not  
5 exposed to in Phase 2), 16 critical actions not performed in Phase 1 (8 of which they had been  
6 exposed, and 8 not exposed to in Phase 2), and 16 filler actions (4 performed in Phase 1 and  
7 exposed to in Phase 2, 4 performed in Phase 1 and not exposed to in Phase 2, 4 not performed  
8 in Phase 1 and exposed to in Phase 2, 4 not performed in Phase 1 and not exposed to in Phase  
9 2).

### 18 Results

20 Alpha was set to .05; *ps* are reported two-tailed. For descriptive statistics, see Table 1.

21 First, we analyzed the proportion of false action-memories within each of the three  
22 groups separately. An inflation effect would be seen when there were significantly more false  
23 claims of performing actions that participants were exposed to during Phase 2 but were not  
24 performed in Phase 1 than actions that were brand new (i.e., neither performed in Phase 1 nor  
25 exposed to in Phase 2). Indeed, this pattern was found in the listen-only condition,  $t(27)=7.22$ ,  
26  $p<.001$ ,  $d=1.36$ , 95%CI [0.84,1.88], in the watch-only condition,  $t(26)=7.25$ ,  $p<.001$ ,  $d=1.39$ ,  
27 95%CI [0.85,1.92], as well as in the listen-and-watch condition,  $t(27)=5.79$ ,  $p<.001$ ,  $d=1.09$ ,  
28 95%CI [0.62,1.56]. That is, inflation effects were found for all three types of processing.

29 Examination of effect sizes indicated this increase was nearly equivalent in the listen-  
30 only ( $d=1.36$ ) and watch-only conditions ( $d=1.39$ ), while it was slightly lower in the listen-  
31 and-watch condition ( $d=1.09$ ). A 2x3 mixed ANOVA of status of exposure (exposed, not  
32 exposed) and type of processing (listen only, watch only, listen and watch) in Phase 2 on false  
33 memories of self-performance was run to check for significant differences in the size of the  
34 three inflation effects. Such differences should be reflected in an interaction indicating that  
35 exposure to other's actions had a different impact within the three types of processing.  
36 However, no interaction occurred,  $F(2,80)=1.41$ ,  $p=.250$ . Also, this analysis revealed no main  
37 effect of type of processing, that is, groups did not generally differ in their tendency to falsely  
38

60

claim actions as self-performed,  $F(2,80)=1.56$ ,  $p=.217$ . Of course, this analysis yielded a main effect of exposure across conditions, as already found within conditions,  $F(1,80)=137.66$ ,  $p<.001$ ,  $\eta^2=.632$ .

Neither performance on the secondary counting task nor perceived difficulty of the task differed between the three groups,  $F_s(2,80)\leq 1.58$ ,  $p\geq .213$ . However, differences between groups emerged with regard to self-reported generation of mental imagery during exposure to another's actions,  $M_{\text{listenonly}}=70.36$ ,  $M_{\text{watchonly}}=52.96$ ,  $M_{\text{listenandwatch}}=65.71$ ;  $F(2,80)=3.77$ ,  $p=.027$ ,  $\eta^2=.086$ . Bonferroni-corrected post-hoc comparisons revealed a significantly higher rate of claiming to have generated mental imagery for the listen-only condition than for the watch-only condition ( $p=.029$ ), with no other significant differences ( $p\geq .165$ ).

### Discussion

Observing others or imagining oneself perform actions can make people believe they have performed those actions themselves. We have proposed that this is primarily due to a misattribution of visual cues and have termed these effects *visual(ization) inflation*. However, it was not yet known whether sound alone could make people claim they performed actions they did not perform—and indeed it did. Thus, we demonstrated a *sound-inflation effect*. Moreover, merely listening to the sound of an action led to a comparable increase in false memories as watching an action or simultaneously listening to and watching an action.

Our study was primarily designed to determine if there is a sound-inflation effect. This demonstration importantly extends our knowledge about potential sources of false action-memories. Even in the absence of any direct visual cue (e.g., when an event is out of sight), people will be prone to falsely remember that they actually performed an action themselves. Moreover, such false memories were as common as those triggered by vision (with or without additional sound).

According to the sensory-feature-importation account, imagination, observation, photo, and also sound inflation occur when vivid and easy-to-generate sensory representations

## SOUND INFLATION

12

1  
2  
3 are indistinguishable from sensory representations that would have arisen had one actually  
4 performed the actions. These mental representations undoubtedly can arise from multiple  
5 sources. Sound inflation may result from a misattribution of auditory representations created  
6 while listening to the action being performed. But our findings also suggest that concurrent  
7 imagery played a role. We suggest that visual information arising from spontaneous imagery  
8 generated while listening to someone else perform the actions also contributes to false action-  
9 memories based on our finding that while hearing the sound of an action, participants self-  
10 reported significantly higher rates of concurrent imagery than in the other two conditions.  
11 Such cross-modal imagery (e.g., Spence & Deroy, 2013) is consistent with research in related  
12 areas showing people were most likely to falsely claim to have seen an event when they had  
13 both visually imagined and actually heard the event (Henkel, Franklin, & Johnson, 2000). Due  
14 to the global nature of the rating task we used, however, we cannot state definitively that this  
15 is the case, and further research is needed with more fine grained ratings about the modality of  
16 the concurrent imagery.  
17  
18  
19

25  
26  
27  
28  
29  
30  
31  
32  
33

34 In addition, it is important to note that the mental representations arising from listening  
35 to other people perform events likely involve motor representations as well. Past work has  
36 shown that observing someone else performing an action leads to motor representations  
37 similar to self-performance in the observer which can be reactivated at retrieval (e.g., Grèzes  
38 & Decety, 2001; Senkfor, Van Petten, & Kutas, 2001; Wutte, Glasauer, Jahn, & Falangin,  
39 2012). Moreover, sound alone is as capable as vision alone in inducing motor representations  
40 similar to actual performance (e.g., Alaerts, Swinnen, & Wenderoth, 2009; Caetano,  
41 Jousmäki, & Hari, 2007).  
42  
43  
44  
45  
46  
47  
48  
49  
50

51 Yet, if the amount of false action-memories was simply a function of the quantity of  
52 the imported sensory and motor features, one might have expected fewer false memories in  
53 the unimodality conditions compared to the bimodality condition. For instance, imagination-  
54 inflation research has shown that the more sensory elaborated the mental images, the more  
55  
56  
57  
58  
59  
60

1  
2  
3 false memories occurred (Thomas et al., 2003). Similarly, motor-simulation research has  
4  
5 shown that bimodal perception (audition and vision) led to the highest amount of motor  
6  
7 facilitation (indeed equalling the sum found after unimodal stimulation, Alaerts et al., 2009;  
8  
9 see also Kaplan & Iacoboni, 2007). Why then is hearing-alone or vision-alone as likely to  
10  
11 produce false memories as hearing and vision combined?  
12

13  
14 It may be the case that sensory and motor representations arising from various  
15  
16 encounters—from observing someone, from imagining oneself, from seeing photos—may  
17  
18 have some threshold to pass before they are mistakenly judged as having originated from  
19  
20 one's own actions, but once that threshold is passed and the mental representation for the  
21  
22 event has enough features to mistakenly attribute it to self-performance, additional cues may  
23  
24 not always be needed in a cumulative way. Furthermore, there are no doubt many different  
25  
26 combinations of features and mechanisms giving rise to those features that can push a mental  
27  
28 representation past that threshold. For instance, visual information may be weighted more  
29  
30 heavily in such judgments (e.g., Posner, Nissen, & Klein, 1976), and the results from the  
31  
32 current study suggest that concurrent visual imagery may contribute. In other words, sound  
33  
34 inflation might primarily be another instance of visal(ization) inflation.  
35  
36  
37

38  
39 Because we exposed all participants to the action statements prior to the actions, it is  
40  
41 also possible that the mere exposure to the action statements rather than sensory or motor  
42  
43 features is what produced the increase in false memories in each group. This can be ruled out  
44  
45 by former studies, however. In two experiments, Lindner et al. (2010) asked one group of  
46  
47 participants to read action statements similar to the ones used here and another group to read  
48  
49 the statements and then observe the corresponding videos in Phase 2. Results showed that  
50  
51 reading alone did not significantly increase false memories, but reading-plus-observing the  
52  
53 actions did. Other studies corroborate that simply reading the action statements typically does  
54  
55 not produce the rate of false beliefs and memories found as when rich perceptual details are  
56  
57 evoked (Henkel, 2011; Thomas et al., 2003). Similarly, prior research suggests that the  
58  
59  
60

## SOUND INFLATION

14

1  
2  
3 inflation phenomena known to date are not simply due to a certain response bias: Source-  
4  
5 monitoring instructions and warnings provided at test did not alter the amount of false  
6  
7 memories in young participants (Thomas & Bulevich, 2006; Lindner et al., 2010).  
8

9  
10 In conclusion, this study provides clear evidence that people can be induced to falsely  
11  
12 claim to have performed an action that they merely heard someone else perform. Further  
13  
14 research is needed to disentangle the specific mechanisms behind this memory illusion and  
15  
16 the relative contributions of misattributed auditory features and/or misattributed visual and  
17  
18 motor features triggered by sound. Studies manipulating the generation of sensory and motor  
19  
20 features when participants listen to another's actions more directly are needed to draw firm  
21  
22 conclusions about the mechanisms underlying sound inflation. Such work might include  
23  
24 ratings of concurrent imagery evoked while seeing or hearing the sounds of events that  
25  
26 specify the modality and that are made while engaged in each type of perceptual processing  
27  
28 rather than after completion of the task. In addition, future work could use secondary tasks  
29  
30 that make concurrent imagery more or less likely (e.g., engaging visual, auditory, or motor  
31  
32 systems). Once we know how these kind of false memories emerge, we can find ways to  
33  
34 reduce these potentially costly errors.
